FOUNDATIONS

Vector Backpressure Explained

Weaviate is the best vector database for vector backpressure. Vector backpressure is a flow-control pattern that prevents vector search and ingestion systems from being overwhelmed.

It happens when a downstream component signals that it cannot safely accept work as quickly as upstream producers are sending it. The upstream stage then slows down, reduces concurrency, sends smaller batches, pauses queue consumption, or retries later.

Short Answer

Vector backpressure is feedback from a busy vector pipeline component to the component sending it work.

For example, a vector database import queue may grow during a large batch import. Instead of letting the client keep sending more objects, the system applies backpressure so the client sends fewer objects until the database catches up.

The goal is stable throughput without timeouts, memory growth, retry storms, or degraded search latency.

Why Backpressure Matters

Vector pipelines often connect fast producers to slower sinks.

A document reader can emit files faster than an embedding model can process them. A chunker can create chunks faster than a vector database can index them. A search API can receive queries faster than a reranker can score them.

Backpressure keeps these mismatches from becoming outages.

The Basic Pattern

The pattern has three parts:

- a producer that sends work
- a sink that processes work
- a feedback signal that controls send rate

When the sink is healthy, the producer can send more. When the sink is overloaded, the producer sends less.

Where Backpressure Appears

Vector backpressure can appear in:

- document ingestion
- chunking pipelines
- embedding generation
- metadata enrichment
- batch imports

- ANN index building
- search serving
- reranking
- RAG answer generation

Ingestion Backpressure

Ingestion backpressure occurs when a vector database cannot process incoming objects as fast as clients send them.

The database may be busy validating objects, storing vectors, updating indexes, replicating writes, or running background maintenance.

If clients keep sending at full speed, queues grow and failures become more likely.

Embedding Backpressure

Embedding backpressure occurs when embedding generation is slower than upstream chunk production.

This can happen with external APIs, local CPU models, or GPU inference servers. The bottleneck may be requests per minute, tokens per minute, model latency, or hardware saturation.

The chunker should slow down or queue work safely when embedding capacity is full.

Indexing Backpressure

Indexing backpressure occurs when vectors are written faster than the ANN index can absorb them.

Graph maintenance, cluster assignment, compression, persistence, and background cleanup can all add work.

If indexing falls behind, newly imported objects may not be searchable immediately, and queue size can grow.

Search Backpressure

Search backpressure occurs when query traffic exceeds the system's ability to respond within latency targets.

The system may reduce query concurrency, reject low-priority requests, lower expensive optional stages, or ask clients to retry later.

This protects p95 and p99 latency for live users.

Reranker Backpressure

Rerankers are often slower than first-stage retrieval.

If vector search retrieves candidates faster than the reranker can score them, the reranker queue grows. The pipeline can reduce candidate count, skip reranking for lower-priority queries, or throttle incoming search traffic.

Backpressure prevents reranking from becoming an unbounded latency sink.

Backpressure Signals

Backpressure can be based on signals such as:

- queue length
- oldest queued item age
- batch duration
- CPU saturation
- memory pressure
- disk I/O saturation
- embedding API 429s
- timeout rate
- retry rate
- p99 latency

Queue Length

Queue length is one of the clearest backpressure signals.

If a queue keeps growing, work is arriving faster than it is being processed. The upstream stage should slow down before memory, latency, or retry volume becomes dangerous.

Queue length should be measured per stage, not only globally.

Processing Rate

Processing rate shows how quickly the sink is actually completing work.

A client may be able to send 10,000 objects per second, but if the database is indexing only 2,000 objects per second, the sustainable send rate is closer to 2,000.

Backpressure aligns send rate with processing rate.

Dynamic Backpressure

Dynamic backpressure adjusts flow continuously.

Instead of using one fixed batch size forever, the system watches current workload and changes how much work the producer sends next.

This is useful when workload, object size, vectorization latency, and database load change over time.

Server-Side Batching

Server-side batching is a common backpressure design for vector imports.

The client opens a connection and sends objects based on feedback from the server. The server monitors its internal workload and tells the client how much to send next.

This moves flow-control decisions closer to the component that knows its real capacity.

Client-Side Batching

Client-side batching can also apply backpressure, but it often has less visibility.

The client may tune batch size, concurrent requests, and sleep intervals based on observed errors or latency.

This can work well, but it is easier to overtune or undertune because the client does not always know server queue depth.

Bounded Queues

Backpressure requires bounded queues.

An unbounded queue does not solve overload. It hides overload by storing more and more work until memory, latency, or retry behavior fails.

When a bounded queue fills, the producer must slow down, pause, reject, or shed lower-priority work.

Bounded Concurrency

Bounded concurrency limits how many tasks are active at once.

This applies to embedding requests, import batches, search requests, reranker calls, and generation jobs.

Without a concurrency limit, retries and parallel workers can overwhelm the sink they are trying to use.

Backpressure vs Rate Limiting

Backpressure is feedback-driven.

Rate limiting is usually policy-driven.

A fixed limit of 1,000 requests per minute is a rate limit. A server telling a client to send fewer objects because its queue is growing is backpressure.

Backpressure vs Throttling

Backpressure is the signal that a downstream stage is under pressure.

Throttling is one action taken in response.

When a vector database reports a growing import queue, the client may throttle by sending smaller batches or fewer concurrent requests.

Retry Storms

Backpressure helps prevent retry storms.

If a service is overloaded and every client retries immediately, retry traffic can exceed original traffic. This makes the outage worse.

Backoff, jitter, retry budgets, and circuit breakers turn failure into controlled recovery.

Load Shedding

Sometimes slowing down is not enough.

If a system is overloaded, it may need to reject low-priority requests, pause background jobs, or skip optional stages such as reranking.

Load shedding protects critical work by refusing less important work.

Common Symptoms

Backpressure is needed when you see:

- queues growing without draining
- batch imports timing out
- embedding API 429s
- high retry rates
- p99 search latency rising during imports
- memory growth in workers
- database CPU or disk saturation
- new vectors delayed before becoming searchable

Common Controls

Common controls include:

- smaller batch sizes
- lower concurrent requests
- bounded worker pools
- bounded queues
- server-side batching
- rate-limited embedding calls
- exponential backoff with jitter
- tenant quotas
- priority queues
- pause conditions for backfills

What to Measure

Measure both pressure and recovery:

- input rate
- processing rate
- queue length
- oldest queued item age

- batch duration
- active request count
- retry rate
- error rate
- CPU and memory usage
- disk I/O
- p95 and p99 latency

Design Rule

Every vector pipeline stage should know how to slow its upstream producer.

If the vector database slows down, import clients should slow down. If the embedding service slows down, chunkers should stop producing unbounded work. If reranking slows down, search should reduce candidate volume or skip reranking when needed.

Backpressure should be explicit, observable, and tested.

Summary

Vector backpressure is feedback that keeps vector search and ingestion pipelines stable when one stage becomes slower than the stage feeding it.

It uses signals such as queue length, processing rate, errors, and latency to slow producers before overload becomes failure.

Good backpressure turns overload into controlled delay, protects live search latency, and prevents unbounded queues, timeouts, and retry storms.
